1. Basic Concepts of Nuclear Power

Nuclear power reactors harness the heat generated by splitting atoms of certain elements in a controlled and predictable way. This heat is used to create electrical power¹.

1.1. Fission

Nuclear fission is the spontaneous or induced reaction, by which an atom is broken up. In the case of nuclear power reactors, these reactions are exothermic. Nuclear radiation such as in equation 1.1 already liberates a large amount of energy.

$${}_{92}^{238}\text{U} \rightarrow {}_{90}^{234}\text{Th} + \alpha, \quad P = 8 \cdot 10^{-9} \frac{W}{g} \quad (1.1)$$

This power is increased in nuclear reactors by 10 orders of magnitude. Although the effective lifespan is lowered from $4.468 \cdot 10^9$ years to a few months. Therefore fission is the main reaction through which nuclear reactors generate the majority of their power output. An example of such a reaction is given in equation 1.2.²

It is important to note that 1.2 is a simplification of the actual decay series of ${}_{92}^{236}\text{U}$ into stable end products. 1.2 is sufficient to understand the principle

¹World Nuclear Association, 2022.

²Basdevant, Rich, and Spiro, 2005, p. 286.

1. Basic Concepts of Nuclear Power

behind nuclear fission. A decay series of $^{236}_{92}\text{U}$ with no intermediates removed is given in 1.3.³

1.2. Nuclear Cross Section

Nuclear cross section describes the probability of a certain nuclear reaction to occur. This aspect needs thorough consideration in the design of nuclear reactors, as the nuclear cross section generally increases with the inverse of the velocities of the reactants⁴.

1.3. Criticality

Criticality is the operating condition of a nuclear reactor, in which the neutrons produced by fission events is sufficient to sustain a chain reaction. It is measured using the multiplication factor k . It is defined as in 1.4. If the factor k equals 1 the reaction is said to be critical. In a critical reaction, the number of neutrons causing a fission event remains constant. If the factor k is less than 1, the number of neutrons is decreasing and the chain reaction is said to be subcritical. If the factor k is greater than 1 the number of neutrons is increasing exponentially and the reaction is supercritical.^{5,6}

$$k = \frac{\text{number of neutrons involved in fission in generation } n}{\text{number of neutrons involved in fission in generation } n - 1}\tag{1.4}$$

⁴Basdevant, Rich, and Spiro, 2005, p. 108.

⁵Basdevant, Rich, and Spiro, 2005, p. 308.

⁶Stacey, 2018, p. 39.

1. Basic Concepts of Nuclear Power

In practice the reactivity ρ is used. It describes the change of the reactor away from the critical state. It is calculated using 1.5.

$$\rho = \frac{k - 1}{k} \quad (1.5)$$

1.4. Safety

Safety is particularly important for nuclear power reactors, as they contain large amounts of radioactive material, which could be released into the environment in the case of an accident. During the ongoing fission reaction a large amount of radioactive isotopes, of which actinides are the most dangerous. Thus safety in nuclear power plants has three main objectives. Firstly, the reactor needs to operate normally without exposing operators and the environment to dangerous levels of radiation. Secondly, accidents need to be prevented as much as possible. Thirdly, in the case of an accident the consequences need to be minimized. Therefore for each reactors risks need to be carefully evaluated and their probabilities need to be carefully considered⁷.

1.5. Efficiency

Like other power plants, current nuclear power reactors offer efficiencies between 30% and 35%. However with increased heat and cogeneration the efficiency of nuclear power plants could be increased dramatically⁸.

1.5.1. Cogeneration

Usually a large amount of energy is lost to the environment in the form of heat. This is usually destructive towards the environment and results in reduced efficiency. This heat could be used in cogeneration to supply heating to other

facilities or private housing, thereby reducing the amount of wasted, unused energy⁹.

1.5.2. Capacity Factor

TODO

1.6. Components of Nuclear Reactors

1.6.1. Fuel

The reactor fuel is the fissile material used in the fission reaction inside of a reactor. In most cases uranium dioxide UO_2 pressed into pellets is used for this purpose. These pellets are put into tubular fuel rods. The whole fuel assembly inside the reactor consists of many such rods¹⁰.

1.6.1.1. Startup Neutron Source

As the fission of uranium produces on average 2.4 neutrons per reaction, there does not need to be a constant external influx of neutrons. However, to start this chain reaction inside a new reactor equipped with newly made fuel rods a neutron source is needed. Usually beryllium combined with an alpha emitter is used for this purpose, as the collision of an α -particle with ${}^9_4\text{Be}$ releases a neutron as part of its reaction, as can be seen in equation 1.6^{11,12}.

¹²Basdevant, Rich, and Spiro, 2005, p. 100.

Figure 1.1.: Nuclear cross section of ^{235}U in relation to neutron energy

1.6.2. Moderator

Nuclear fission events release neutrons with energies in excess of multiple MeV, or speeds higher than $10^7 \frac{m}{s}$. However at these speeds the nuclear cross section of the fission reaction is quite low as can be seen in figure 1.1.

Therefore the emitted neutrons need to be slowed down in order to be useful. These are called thermal neutrons. This is done using a moderator. When passing through a moderator the neutrons are slowed down through collisions with the aforementioned. Although it is important to note that the moderator should absorb as few neutrons as possible to not hinder the chain reaction. For this reason H_2O and graphite are commonly used.¹³

1.6.2.1. Fast Reactors

However, there is a category of reactors which harness fast neutrons in their nuclear reaction. These have no moderator and instead make use of fuel, which

¹³Stacey, 2018, p. 28.

1. Basic Concepts of Nuclear Power

requires a higher share of ^{235}U as this reduces the chance of neutron capture by ^{238}U and increases the likelihood of a fission event to occur. As actinides are fissile by fast neutrons, fast reactors may reduce the amount of transuranic nuclear waste generated by nuclear power production. There is still ongoing research regarding fast reactors to make them useful for widespread energy production.¹⁴

1.6.3. Control Rods or Blades

In order to regulate the reaction speed inside of a nuclear reactor the number of neutrons inducing nuclear fission needs to be regulated. This is accomplished using control rods. As a single control rod with a circular cross section would lead to very nonuniform fission and temperature dynamics, the control rods are either arranged into cruciform blades or evenly spaced across the reactor in the form of clusters. A typical reactor contains around 50 clusters, each made up of 20 control rods^{15,16}.

These rods or blades contain materials which readily absorb neutrons, such as boron or cadmium. They may either be made of steel enriched with boron or hollow tubes filled with a brittle salt like material such as cadmium isotopes. Because the amount of fuel inside reactor steadily decreases, the amount of neutrons absorbed needs to be regulated in order for the chain reaction to continue. Therefore the control rods or blades are mounted on a movable apparatus, which extends or retracts the control rods into or out of the reactor, thereby regulating the amount of neutrons absorbed¹⁷.

1.6.4. Coolant

The coolant is a liquid which circulates inside the nuclear reactor core to extract the thermal energy generated from the fission reactions. In most cases today this liquid is H_2O . In the case of boiling water reactors the water is boiled

1. Basic Concepts of Nuclear Power

directly inside the core. In all other reactor types, such as pressurized water reactors at least a secondary, separated, coolant circuit is used, which transports the heat away from the primary circuit. When the water is not boiled inside the reactor core, a separate steam generator is used to create the steam, which drives the turbine. The same water which is used as a coolant may also be used as the reactor moderator¹⁸.

¹⁸World Nuclear Association, 2022.

2. Historical Generational Developments of Nuclear Reactors

Nuclear reactors are normally categorised into generations. These generations differentiate reactors based on various technological factors such as cost-effectiveness, safety, commercial applicability and fuel cycle. These generations present a useful tool in categorizing nuclear reactors as multiple factors are combined into one single metric. It is important to note that all designs of generations I to III+ consist mainly of designs first developed in the late fourth decade of the 20th century with various improvements added.¹ Figure 2.1 shows a timeline of nuclear reactor generations along with important notes on the properties of reactors in this generation. The images show representatives of each generation. It is important to note that the example image for gen-

Figure 2.1.: Timeline of nuclear reactor generations

¹Goldberg and R., 2011, pp. 1, 2.

2. Historical Generational Developments of Nuclear Reactors

eration IV is not representative, as the reactors of this generation are still in development and have not been built.

2.1. Generation I

The first generation of nuclear reactors consists primarily of research reactors and primitive nuclear power plants. These reactors are regarded as “proof of concept” in the USA. All reactors of this generation have been decommissioned or are undergoing deconstruction as their technological level is far behind that of newer reactors. Therefore they have very low cost-effectiveness and operational safety².

2.2. Generation II

The second generation of nuclear reactors represent the first efforts to produce nuclear reactors primarily designed for commercial viability. They comprise mainly boiling water reactors (BWR), pressurised water reactors (PWR), Canadian deuterium uranium reactors (CANDU) and advanced gas-cooled reactors (AGR). They are designed for an operational lifetime of 40 years. Generation II reactors are the most common generation for boiling water reactors and pressurised water reactors around the world, which can be categorised under the term light water reactor (LWR). These reactors feature more advanced safety features compared to generation I reactors. These safety features have the ability to automatically prevent grievous incidents in the operation of a nuclear reactor, as they prevent dangerous incidents in cases such as loss of power or operator error.

Designs from this category require comparatively large electrical power grids. And feature advanced safety envelopes based on western standards. New reactors of this generation are mainly built in China, Russia and the Republic of Korea. Their fuel cycle requires high level waste repositories for ultimate disposition³.

²Goldberg and R., 2011, p. 3.

³Goldberg and R., 2011, pp. 4–6.

2.3. Generation III

In essence nuclear reactors of the third generation are the same designs as in the second generation with evolutionary improvements. These reactors feature improvements to fuel economy, thermal efficiency and safety. These designs shift away from active safety systems to passive safety systems. They also feature a more standardised design, which leads to more economical construction costs. Designs such as the advanced boiling water reactor (ABWR) belong to this generation⁴.

2.4. Generation III+

As implied by the name nuclear reactors of the III+ generation feature another set of incremental improvements over the third generation. The main focus of these improvements lay in the improved safety of reactor systems as less operator intervention and fewer active components are utilized in reactor safety systems. These new safety systems utilize effects such as gravity to function. This leads to improved safety as a total failure of these safety systems is very unlikely compared to those of earlier generations. These reactors also have a higher expected operating lifetime of up to 60 years. The power plants of this generation also have increased fuel burn up. This has the consequence of reducing fuel consumption and reduced waste generation. Many reactors of this generation of different designs are in operation and construction around the globe⁵.

⁴Goldberg and R., 2011, pp. 5, 6.

⁵Goldberg and R., 2011, pp. 7–11.

3. Common Nuclear Reactor Types in Current Use

3.1. PWR – Pressurized Water Reactor

Pressurized water reactors harness H_2O as coolant and commonly also as moderator. However they have at least two coolant circuits. The water in the primary coolant circuit is under a large pressure in order to still remain liquid even at the high temperatures generated inside the reactor core. Between the primary and secondary coolant circuit lay a steam generator, which turns the cool water supplied in the secondary circuit into steam used to drive turbines. Special attention needs to be drawn to the fact, that primary and secondary circuit are never directly connected and therefore no radioactive material can be passed from inside the reactor core through the steam generator. Therefore only the reactor components which lay before the steam generator need to be under containment.^{1,2} A simplified schematic representation of a pressurized water reactor can be seen in 3.1. The turbine and cooling systems of every schematic are not shown, as this would exceed the scope of the explanations given herein and not contribute to the understanding of the reactor types shown.

¹World Nuclear Association, 2022.

²Khalil, 2016, pp. 14-84.

3. Common Nuclear Reactor Types in Current Use

Figure 3.1.: Schematic representation of a pressurized water reactor

3.2. BWR – Boiling Water Reactor

Boiling water reactors are characterized by their mode of steam production. In comparison to pressurized water reactors, these reactors boil the water directly inside the reactor core. This has the advantage of significantly increasing the simplicity of reactor construction, because there is no need for a steam generator or secondary coolant loop. Like pressurized water reactors, boiling water reactors most commonly employ water as their moderator. Because the coolant water unavoidably comes into direct contact with the fuel rods, radioactive isotopes are leaked into the coolant water and therefore turbines. But as these isotopes almost unanimously consist of ^{16}N , which has a short half life of 7 seconds, the access radiation is almost completely depleted after power generation. But due to the further spread of radioactive material a greater area of containment needs to be constructed for the nuclear power plant³. A schematic representation of a boiling water reactor is shown in 3.2

³Khalil, 2016, pp. 85–140.

3. Common Nuclear Reactor Types in Current Use

Figure 3.2.: Schematic representation of a boiling water reactor

3.3. PHWR – Pressurized Heavy Water Reactor

Pressurized heavy water reactors also called CANDU for Canadian deuterium uranium reactor, utilize heavy water (${}^3_1\text{H}_2\text{O}$ – also called D_2O) as coolant and moderator. The cylindrical fuel elements, which consist of multiple small fuel rods welded together, as shown in 3.4, rest inside zirconium alloy pressure tubes, through which the cooling heavy water flows. Many of these tubes are contained inside the calandria. The calandria itself is an enclosed chamber, which contains low pressure, low temperature heavy water used only as moderator. Because only the heavy water inside the zirconium alloy pressure tubes is under high pressure, the calandria need not be able to withstand the pressures, which are exerted upon the vessels housing pressurize water reactors and heavy water reactors. The only parts which need to withstand high mechanical stress are the pressure tubes, which can more easily be mass manufactured, due to their repetitiveness. Another advantage of this design is that single tubes can be refueled during reactor operation, as they can be disconnected, while other reactor designs need to be shut down completely before a change of fuel rods can occur. Pressurized heavy water reactors can also operate on unenriched
